Vitellogenin Assay by Enzyme-Linked Immunosorbant Assay as a Biomarker of Endocrine Disruptor Chemicals Pollution

Mansour Ebrahimim
Green Research Center, University of QOM, QOM, Iran

Abstract: Research is ongoing to develop screening and testing programmes for endocrine disrupting effects of new chemicals and in the focus of this development are the fish test species common carp (Cyprinus carpio). In this study we have developed quantitative enzyme linked immunosorbent assays (ELISA) for VTG in common carp. The working range of the ELISA was 11.25 to 2,000 ng mL\(^{-1}\) (75-25% specific binding/maximum antibody binding [B/B0]) with a 50% B/B0 intra- and interassay variation of 3.9% (n = 10) and 12.5% (n = 30), respectively. This ELISA is capable of detecting VTG as low as 6 ng mL\(^{-1}\) and can accurately detect VTG in even 10 µL of plasma. The ELISA was applied to measurement of VTG production by male carp (Cyprinus carpio, Cyprinidae) fish exposure to ethynylestradiol. The results showed that the amount of VTG produced in plasma of exposed fish increased in logarithmic order comparing to the control group and the ELISA described here could be used as an indicator of water pollution to estrogenic pollutants.

Key words: Immunoassay, ELISA, endocrine disruptor chemicals, VTG

INTRODUCTION

The last two decades have witnessed growing scientific concern and public debate over the potential adverse effects that may result from exposure to a group of chemicals that have the potential to alter the normal functioning of the endocrine system in wildlife and humans (Tsutsumi, 2000). According to WHO definition, an Endocrine Disruptor Chemical (EDC) is an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub)populations (Dumstra et al., 2002).

Mammalian studies have focused on the male since it is much easier to determine changes in the quality and quantity of sperm than of eggs, since eggs are few and are retained internally (Lathers, 2002). Fish have a major advantage over mammals in studies of endocrine disruptors in that they produce large numbers of both eggs and sperm and release them to the external environment. An assessment of pollution requires a simple biomarker and VTG can be the easiest choice.

In very simple terms, vitellogenesis involves ovarian estradiol stimulating the liver to produce VTG, which in turn is incorporated into the yolk of developing oocytes. Estrogenic xenobiotics can also act on the hepatic receptors to induce synthesis of VTG (Nakari, 2004). Both male and female fish, as well as immature juveniles have hepatic estrogen receptors, but only the livers of female fish will normally be exposed to estrogens (Versenon and Janssen, 2004). Production of VTG by males and juveniles, or non-vitellogenic females can therefore provide a biomarker of exposure to environmental estrogens (Hornung et al., 2004).

Trout exposed to sewage effluent in English rivers had up to 100,000-fold increase in plasma VTG compared to fish upstream of the effluent (Aermi et al., 2004). A follow-up study showed VTG levels of over 20 mg mL\(^{-1}\) 5 km downstream of the effluent (Sharpe et al., 2004). Elevated plasma VTG was also found in eels below the Paris outfall (Versenon et al., 2004). Since eels may spend up to 20 years in the river before their spawning migration consequence reproductive disruption may account for some of the decrease in the European eel population (Versenon et al., 2004). The flounder, as a bottom dwelling estuarine species, also provides a useful biomonitor of effluents in the rivers which may potentially affect marine fish stocks (Madsen et al., 2003). In another study, male flounder in a number of British rivers had elevated plasma VTG and, in the River Mersey, the concentrations were around 100 mg mL\(^{-1}\) (10 million times higher than controls) (George et al., 2004).

Enzyme Linked ImmunoSorbent Assay (ELISA) using microtiter plates have been described as an alternative to radioimmunoassay for the mammalian and non mammalian assays (Yamada et al., 2002) and to monitor the effects of endocrine disrupting chemicals on reproductive function (Wade et al., 2002) and a report (Tattersfield et al., 1997)
has highlighted the need for a simple, rapid and reliable method for the measurement of hormones in this communication we describe a general preparation procedure for the enzyme label of carp VTG which is applicable to other species. The method was applied to the determination of VTG production by ethynylestradiol, a potent xenoestrogen, in Carp (Cyprinus carpio) plasma.

MATERIALS AND METHODS

Chemicals and equipment: Cyprinus carpio VTG and anti-VTG antibodies were a kind gift from: professor Oliva Carnevali, Dipartimento di Biologia MCA, University of Camerino, 62032 Camerino, Italy. The purified VTG is diluted to 10 and 50 mg mL\(^{-1}\) with VTG storage buffer (PPBS, 0.1M, pH 7.4, Potassium chloride, 27 mM; Tween-20, 0.05%; Bovine Serum Albumin, 0.2%; Sodium Azide, 5 mM; Aprotinin, 20 IU mL\(^{-1}\), 1% (Sigma)), divided into various volumes in eppendorf tubes and stored at -20°C. Goat F(ab')2 fragment of affinity isolated rabbit antigen specific antibody conjugated to alkaline phosphatase was obtained from Sigma Immuno Chemicals (catalogue number A-3937). 4-Nitrophenylphosphate (pNPP) obtained from Boehringer Mannheim GmbH (catalogue number 107 905).

Ninety-six well polystyrene high-binding microliter plates (Costar Catalogue No. 3950) were used for the ELISA. Plates were sealed for storage with Anachem Sealplate sealing film. Plates were processed using a Chelsea Instruments shaker, an Anthos Model AW-1 plate washer and read with an Anthos Model HTII Plate Reader. 96-well low binding microliter plates (Costar Cat. No. 2501) were used for sample dilution and preparation of standard curves and Anachem® SEALPLATE plate sealing film, (PK/100) purchased from Anachem (UK).

Fish exposure: Four groups of six male common carp (initial mean weight: 268.9 ±52.5 g, mean±SD) originating from a local fish breeder farm (Mahyar company) kept in four separate tanks. They were exposed to 0, 5, 10 and 50 ng mL\(^{-1}\) ethynylestradiol up to 30 days. Blood samples were taken at 0, 15 and 30 days of exposure and plasma kept at -20°C until VTG assay.

Plate coating with VTG: LISA plates were coated with 50 ng of purified VTG. One hundred microliter of carbonate buffer (0.05M, pH 9.6) containing 500 ng per mL of purified standard VTG added to each well of the plate and incubated for one hour at room temperature in a humid container and then overnight at 4°C and wash once with nanopure water. The plate was blocked by addition of a 200 μL per well of fresh VTG blocking buffer (Potassium Phosphate Buffer (PPB) 0.1M, pH 7.4; Bovine Serum Albumin, 2%; Sodium Azide, 5 mM), washed three times with wash buffer (Potassium phosphate buffered saline (PPBS), 0.02M, pH 7.4; Tween-20, 0.05%) sealed with plate cover and stored at -20°C.

Standard assay procedure: Serial dilutions of purified standard VTG (2000 to 3.9 ng mL\(^{-1}\)) in 100 μL VTG assay buffer were made in the first 10 wells of rows A and B of the coated plate. The remaining 2 wells in these rows were reserved for D0 (0 pg) and Non-Specific Bound (NSB). Ten microliters of the diluted samples from sample dilution plate (2,000 and 2000 times) was pipetted into the remaining 6 rows in duplicate. Twenty microliters of anti-VTG antisera diluted 1/15,000 (carp) in VTG assay buffer was added to all wells apart from NSB wells and made up the wells to 150 μL by VTG assay buffer. The plates sealed and incubated 2 h at room temperature in a humid chamber. Plates were then washed three times with wash buffer and 150 μL of anti-rabbit IgG Alkaline Phosphatase conjugate diluted 1/15,000 in VTG assay buffer added to each well and incubated overnight at 4°C temperature. Plate washed with wash buffer once and then twice with pNPP Substrate buffer (Dithanolamine, 0.5M, pH 9.8; MgCl, 0.5 mM), 175 μL per well of 1 mg per mL 4-Nitrophenylphosphate in pNPP Substrate buffer added and then incubated dark at room temperature until colour developed to around 1.5 ODs (normally approx. Forty five minutes but can be left up to 4 h). The reaction stopped by adding 50 mL of 3 M NaOH and read at 405 nm. Nanograms per mL were calculated for the samples from the standard curve using Stingray software (Dazdaq, Ringmer, UK).

Assay validation: A pool of male common carp (Cyprinus carpio) plasma (500 μL) placed in 100°C water bath for 1 h to denature proteins from the plasma and then centrifuged. One hundred microliter aliquots were pipetted in duplicate into wells on two rows of a microliter plate. Pure VTG was added to one pair of wells to give a concentration of 2000 ng/well, serial dilutions (x2) performed and the samples assayed according to standard procedure. The same procedure was used to assay VTG in by carp exposed to ethynylestradiol (0, 5, 10 and 50 ng mL\(^{-1}\)). SPSS 10 for Windows software (SPSS Inc., 444 N. Michigan Avenue, Chicago, Illinois 60611, USA)
was used for the statistical analysis (t-test) of VTG production in plasma of control fish group (0 ng mL⁻¹ ethynylestradiol) with other experimental groups (5, 10 and 50 ng mL⁻¹ ethynylestradiol) and duration of fish exposure (15 and 30 days).

RESULTS

Standard curves and assay sensitivity: Typical standard curves for VTG showed the working range of the ELISA was 11.25 to 2,000 ng mL⁻¹ (Fig. 1) (75-25% specific binding/maximum antibody binding [B/B₀]) with a 50% B/B₀ intra- and interassay variation of 3.9% (n = 10) (Fig. 2) and 12.5% (n = 30), respectively. This ELISA is capable of detecting VTG as low as 6 ng mL⁻¹.

Assay specificity: There was a strong positive correlation (r=0.999) between the amount of VTG added to deproteinated plasma and the amount found (Fig. 3).

Application to measuring VTG production by carp exposed to ethynylestradiol: VTG was measured in duplicate by ELISA using 10 µL of the diluted plasma (2, 200 and 2000 times) from fish exposed to different concentrations of ethynylestradiol. The amounts of VTG detected by this method for fish exposed to 0, 5, 10 and 50 ng mL⁻¹ of ethynylestradiol were 0, 189±25.9, 3154±684 and 24569±7698 (Mean±Standard Error of Mean for fish exposed for 15 days) and 0, 897±50.6, 12857±1235 and 86354±10423 µg mL⁻¹ (Mean±Standard Error of Mean, for fish exposed for 30 days) respectively (Fig. 4). A clear and

potent estrogenic activity in inducing VTG by fish liver was found with increase in ethynylestradiol concentration exposure and the amount of VTG induced by different concentrations of ethynylestradiol between control (0 ng mL\(^{-1}\)) and experimental (5, 10 and 50 ng mL\(^{-1}\)) groups and between experiment groups were different significantly (p<0.05).

**DISCUSSION**

Examination for the effects of potential EDCs begins only at levels at which there is no apparent stress or discomfort to the animal, so that it is potentially equally able to reproduce (Ackermann et al., 2002). Reproductive dysfunction at such low concentrations can be caused either by direct action on the gametes, or indirectly by modulation of the endocrine system so that gamete development takes place during an imbalance hormonal environment (Okai et al., 2004).

In female fish, endocrine modulators can affect hypothalamic gonadotrophin releasing hormone (GnRH) secretion, pituitary gonadotrophin (G\(\text{H}\)) release, estrogen biosynthesis and catabolism, estrogen binding to hepatic receptors, hepatic VTG production, or the feedback by steroids and VTG (Berg et al., 2004). Although hepatic production of VTG in male fish could be initiated by estrogen hormone, no estrogenic hormones secret in male fish and no VTG production can be expected in normal life (Aerni et al., 2004). The use of *in vitro* fish hepatocyte cultures or *in vivo* fish exposure to estrogenic chemicals is shown to provide a simple and effective way to screen estrogenic activities of EDCs (Tyler et al., 1996). VTG assay in cell culture or fish plasma needs a quick, cheap, reliable and efficient method to fulfill such a duty (Fujita et al., 2004) and many researchers have already introduced different techniques to measure VTG (Anderson et al., 2003, Aerni et al., 2004), an ELISA method for assaying VTG has been described here.

**Assay validation**

**Sensitivity:** Sensitivity of the assays, which has been taken as 90% of the binding with 0 pg is just over 10 \(\mu\)g for VTG. Using identical conditions for label preparation and assay we also obtained a sensitivity of 2 \(\mu\)g for VTG comparable to that obtained by others (Volz and Chandler, 2004). As with radioimmunoassay, the sensitivity is a function of both the specific activity of the label and the quality of the antisera and will therefore vary with the material available to the user. So in this study, we used the antisera that were available to us but have little reason to expect that any antisera which gives good results with RIA will not give similar results to those that we describe for ELISA.

Previous reports of ELISA for VTG have used different enzyme labels (Martin-Diaz et al., 2004) and in this communication a method described previously (Cuisset et al., 1994) and the results showed it is sufficiently sensitive for the rapid measurement of VTG in common fish species such as cyprinids and present an example of such an application was described.

**Accuracy and reproducibility:** A major advantage of ELISA is the ability to minimise errors resulting from multiple pipetting by use of multichannel pipettes. Inter- and intra-assay Coefficient of Variations (CV) reported in RIA are frequently 15-20% even when measured at the steepest part of the curve. For the assays reported here we obtain intra-assay CVs around 3.9% in the steep part of the curve, rising to 15-20% at the flatter end regions (Fig. 2), while interassay variation (at 50% displacement) was around 12%, comparable to that reported by Cuisset et al. (1994). There was a highly significant correlation between the VTG added to and that measured in deproteinized plasma (Fig. 3). A further advantage of ELISA is that sample handling can also be made more rapid and reproducible by the use of low binding microliter plates for sample storage and dispensing with multichannel pipettes.

**Application to the measurement of VTG production in fish:** To demonstrate an application of the ELISA method we have measured the amount of VTG produced by carp exposed to ethynylestradiol. The results confirmed previous findings that ethynylestradiol is a potent estrogenic chemical (Craft et al., 2004) (Fig. 4) and a clear and potent estrogenic activity in inducing VTG by fish was found with increase in ethynylestradiol concentration and the time of exposure (15 versus 30 days) (Fig. 4). The amounts of VTG production in fish exposed increased dramatically so the logarithmic scales used to demonstrate it in Fig. 4. Such a potent induction of VTG in other studies have already been discussed (Versronen et al., 2005).

The rapid determination of VTG from the very small volumes of blood allows the examination of water pollution with EDCs and this methodology will therefore be of great interest to workers screening the estrogenic of new chemicals and phytoestrogens.
