Abstract: In this study, we propose a course-grained NLP approach to text segmentation based on the analysis of lexical cohesion within text. Most research in this area has focused on the discovery of textual units that discuss subtopic structure within documents. In contrast our segmentation task requires the discovery of topical units of text i.e., distinct news stories from broadcast news programmes. Our system SeLeCT first builds a set of lexical chains, in order to model the discourse structure of the text. A boundary detector is then used to search for breaking points in this structure indicated by patterns of cohesive strength and weakness within the text. We evaluate this technique on a test set of concatenated CNN news story transcripts and compare it with an established statistical approach to segmentation called TextTiling.

Key words: Text segmentation, JWordnet, lexical cohesion, statistical word association

INTRODUCTION

Text segmentation can be defined as the automatic identification of boundaries between distinct textual units (segments) in a textual document. The importance and relevance of this task should not be underestimated, as good structural organization of text is often a prerequisite to many important tasks that deal with the management and presentation of data. Consider the usefulness of text segments when responding to a user query in an information retrieval task, where users are given short pieces of relevant text rather than vast quantities of semi relevant documents (Green, 1997). Summarization is another task that can be greatly improved by well-segmented text since the aim of this task is to identify pertinent subtopics in a document and then generate a summary, which encapsulates all of these subtopics (Barzilay and Elhadad, 1997). The main motivation of our research is to investigate whether our lexical chaining technique can be used to segment television news shows into distinct new stories. Lexical chaining is a linguistic technique that uses an auxiliary resource (in our case the JWordNet online thesaurus (Miller *et al*., 1990) to cluster words into sets of semantically related concepts e.g., {motorbike, car, lorry, vehicle}. In this study, we endeavour to explain how such constructs can be used to detect topic shifts in CNN broadcast news programmes extracted from the TDT 1 corpus (Allan *et al*., 1998). The research and results discussed here are a preliminary investigation into the suitability of our lexical chaining technique to the detection of course-grained topic shifts resulting in the identification of news story boundaries. We define a topic shift in this context as the boundary point between two distinct topically cohesive stories. Subtopic or more finely grained topic shifts are those that indicate more subtle thematic changes within a news story e.g. A story on Northern Ireland might report on two separate incidents of violence, however, our system must identify the relationship between these consecutive subtopics and threat them as a single topical unit by returning only one story segment on Northern Ireland. The end goal is to develop a robust segmenter, which will eventually be integrated with a video segmenter (i.e., a system that segments news programmes based on colour analysis) to facilitate the retrieval and playback of individual news stories in response to user requests in the DCU Físchlár system (Smeaton, 2001). In the next study, we discuss in more detail the text segmentation problem and some techniques that have been proposed to solve it. We then describe our model for segmentation based on lexical cohesion analysis. Finally we detail our evaluation methodology followed by results and comparisons with another well established approach to exploratory text segmentation called TextTiling (Hearst, 1997).

TEXT SEGMENTATION

Text segmentation techniques can be roughly separated into two different approaches; those that rely on lexical cohesion and those that rely on statistical

Corresponding Author: S. Lalitha, Sathyabama University, No. 5, Agasthiar Street, Pallikaranai, TamilNadu, India

information extraction techniques such as cue Information Extraction (IE) (Manning, 1998). For IE techniques to work some explicit structure must be present in the text. Manning's segmenter (Manning, 1998) was required to identify boundaries between real estate classified advertisements, which in general will contain the same types of information 'house price' or 'location' etc. As Reynar (1998) remarks in his segmentation work on the TDT 1 corpus, using domain cues in news transcripts such as 'Good Morning', 'stay with us', 'welcome back' or 'reporting from PLACE' are reliable indicators of topic shifts. However the problem with these domain cues is that they are not only genre-specific conventions used in news transcripts but they are also programme specific as well. For example in Irish news broadcasts in contrast to their American counterparts, news programmes are never 'brought to you by a Product name'. Newscaster styles also change across news stations, as certain catch phrases are favored by some individuals more than others. The consequence of this is that new lists of cues must be generated either manually or automatically in which case an annotated corpus is needed. However, as Reynar (1998) points out significant gains can be achieved by combining cue information with other feature information such as named entities (President Bush, George W. Bush Jr), character ngrams (sequences of word forms of length n), and semantic similarity. Reynar like Beeferman *et al.* (1997) developed a machine learning approach which combines cues in a probabilistic framework.

LEXICAL COHESION

Lexical cohesion is one element of a broader linguistic device called cohesion, which is the textual quality responsible for making the sentences of a text seem 'to hang together' (Morris and Hirst, 1991). Here are a number of different forms of lexical cohesion followed by examples from CNN news transcript.

- Repetition-Occurs when a word form is repeated again in a later section of the text e.g. "In Gaza, though, whether the Middle East's old violent cycles continue or not, nothing will ever look quite the same once Yasir Arafat come to town.
- Repetition through synonymy-Occurs when words share the same meaning but have two unique syntactical forms.
- Word association through specialisation/ generalisation-Occurs when a specialised/ generalised form of an earlier word is used.
- Word association through part-whole/whole-part relationships-Occurs when a part-whole/whole-part relationship exists between two words e.g. 'committee' is made up of smaller parts called 'members'.
- Statistical associations between words-these types of relationships occur when the nature of the association between two words cannot be defined in terms of the above relationship types.

LEXICAL COHESION AND TEXT SEGMENTATION

Research has shown that lexical cohesion is a useful device in the detection of subtopic shifts in texts (Hearst, 1997; Ponte and Croft, 1997; Kaufman, 1999; Reynar, 1994; Kozima, 1993). Its suitability to segmentation is based on the fact that portions of text that contain high numbers of semantically related words (cohesively strong links) generally constitute a single topical unit. So in terms of segmentation, areas of low cohesive strength within a text are good indicators of topic transitions. Most approaches to segmentation using lexical cohesion rely on only one form of lexical cohesion i.e., repetition. One such system was developed by Hearst (1997) called Text Tiling. Hearst's algorithm begins by artificially separating text into groups of fixed blocks of pseudosentences (also of fixed length). The algorithm uses the cosine similarity metric to measure cohesive strength between adjacent blocks. Depth scores are then calculated for each block based on the similarity scores between a block and those blocks neighbouring it in the text. The algorithm then deduces boundary points from these scores by hypothesizing that high depth scores (major drops in similarity) indicate topic boundary points. Another interesting approach that implicitly considers all of the above lexical cohesive types is Ponte and Crofts segmenter (Ponte and Croft, 1997). Their segmentation system uses a word co-occurrence technique called LCA (Local Context Analysis) to determine the similarity between adjacent sentences. LCA expands the context surrounding each sentence by finding other words and phrases that occur frequently with these sentence words in the corpus. The authors show that segmentation based on LCA is particularly suited to texts containing extremely short segments which share very few terms due to their brevity. For example, they evaluated their approach on news summaries which had an average sentence length of 2.8. Kaufmann's (1999) VecTiling system augments the basic TextTiling algorithm with a more sophisticated approach to determining block similarity, which is closely related to Ponte and Crofts word expansion technique.

However instead of LCA, VecTile uses Schutze's WordSpace model (Schutze, 1997) to replace words by vectors containing information about the types of contexts that they are most commonly found in.

Lexical chaining on the other hand explicitly considers the first four types of word associations mentioned in this study. We use JWordNet as our lexical resource to facilitate chain creation. As already mentioned lexical chains are essentially groups of words that were cluster together due to the existence of lexicographical relationships between themselves and at least one other member of the chain. For example, in a document concerning cars a typical chain might consist of the following words {BMW, vehicle, engine, wheel, car, automobile, tire}, where each word in the chain is directly or indirectly related to another word by a semantic relationship such as synonymy (car and automobile are semantically equivalent), holonymy (car has-part engine), hyponymy (BMW is a specialization of a car), meronymy (tire is part-of a wheel) and hyponymy (vehicle is a generalization of a car). All these associations can be found in the JWordNet taxonomy. Text segmentation is not a novel application for lexical chaining, in fact in their seminal paper on lexical chain creation using thesaural relations from Roget's thesaurus, Morris and Hirst (1991) detail an algorithm capable of determining 'subtopic flow by recording where in the discourse the bulk of one set of chains ends and a new set of chains begin'. However, it was not until Okumara and Honda's work on the summarization of Japanese text, that Morris and Hirst's approach to segmentation was implemented (Okumura and Honda, 1994). Segmentation research using chains was also briefly discussed by Stairmand in his analysis of lexical cohesion in IR applications (Stairmand and William, 1997).

SELECT - SEGMENTATION USING LEXICAL CHAINING ON TEXT

In this study, we present our topic segmenter, SeLeCT. This system takes a concatenated stream of news programs and returns segments consisting of single news reports. The system consists of three components a 'Tokeniser', a 'Chainer' which creates lexical chains, and a 'Detector' that uses these chains to find news story boundaries.

The tokeniser: The objective of the chain formation process is to build a set of lexical chains that captures the cohesive structure of the input stream. Before work can begin on lexical chain identification each document is processed by a part of speech tagger. Once the nouns in the text have been identified, morphological analysis is performed on these nouns (i.e., all plurals are transformed into their singular state and any compound nouns (consisting of two/three adjacent nouns) are searched for in JWordNet). These part of speech tags also identify potential proper noun entries in the JWordNet thesaurus. In general news story proper noun phrases will not be present in JWordNet, since keeping an up to date repository of such words is a substantial and never ending problem. However, phrases such as 'John Glenn' are present and linked to useful terms like 'senator' and 'astronaut' which when used can significantly improve chaining accuracy.

The lexical chainer: The aim of the chainer is to find relationships between tokens (nouns, proper nouns, compound nouns) in the data set using the JWordNet thesaurus and to then create lexical chains from these associations with respect to a set of chain membership rules. The chaining procedure is based on a single-pass clustering algorithm, where the first token in the input stream forms the first lexical chain and each subsequent token is then added to an existing chain if it is related to at least one other token in that chain by any of the lexicographical relationships defined in this study. In addition a relationship between two tokens is only considered valid if it adheres to the following rules:

- For repetition or synonymy relationships two tokens must appear no more than 600 words away from each other in the original text for the relationship to hold.
- For all other relationships this distance constraint is set to a maximum of 500 words between tokens since they are weaker associations than repetition.
- Further constraints are imposed on relationships between words that have a path length greater than 1 in the JWordNet taxonomy e.g. military action is related to germ warfare by the following relationships: military action is a generalization of war, which is a generalization of bacterial warfare, which is a generalization of germ warfare.

Note: The word distance thresholds above were empirically chosen so as to yield optimal system results.

Imposing a word distance threshold depending on the association between two related words is important for two reasons. Firstly these thresholds lessen the effect of spurious chains, which are weakly cohesive chains containing misidentified word associations due to the ambiguous nature of the word forms i.e. associating bank

with money when bank refers to a river bank is an example of misidentification. The creation of these sorts of chains is undesirable as they add noise to the detection of boundaries described in the next study. Secondly due to the temporal nature of news streams, stories related to important breaking news topics will tend to occur in close proximity in time. If unlimited distance were allowed, even between strongly related words (i.e., where a repetition relationship exists), some chains would span the entire text if two stories discussing the same topic were situated at the beginning and end of a news programme.

Boundary detection: The final step in the segmentation process is to pass all chain information to the boundary detector. Our boundary detection algorithm is a variation on one devised by Okumara and Honda (1994) and is based on the following hypothesis:

'A high concentration of chain begin and end points exist on the boundary between two distinct news stories.' We define boundary strength w(n, n+1) between each sentence in a text (defined as a unit 0 of text that begins with a capital letter and ends with a full stop), as the product of the number of lexical chains whose span ends at sentence n and the number of chains that begin their span at sentence n+1. To illustrate how boundary strengths based on lexical cohesion are calculated consider the following piece of text containing one topic shift (all nouns are highlighted), accompanied by lexical chains derived from this text fragment where chain format is:

{word…… | Sentence number: chain start, chain end}
"Coming up tomorrow when the hearing resumes, we hear testimony from the limousine driver that brought O.J. Simpson to the airport- who brought O.J. Simpson to the airport June 12th, the night of the murders. The **president** of Mothers Against Drunk Driving discusses her **organization's** support of sobriety **checkpoints** over the holiday weekend. She hopes checkpoints will be used all the **time** to limit the **number** of **fatalities** on the **road**."
{hearing, testimony | 1, 1} {tomorrow, night, **holiday**, **weekend**, time | 1, 3}
{airport | 1, 1} {**president**, **organization** | 2, 2} {checkpoints | 2, 3} {murders, **fatalities** | 1, 3}

When all boundary strengths between adjacent sentences have been calculated we then get the mean of all the non-zero cohesive strength scores. This mean value then acts as the minimum allowable boundary strength that must be exceeded if the end of textual unit n is to be classified as the boundary point between two news stories (Fig. 1).

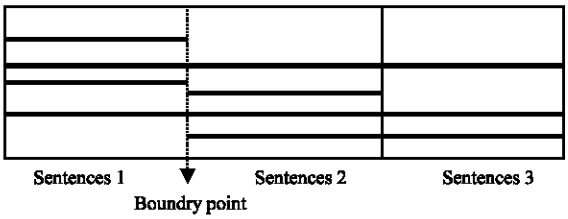

Fig. 1: Chain span schema with boundary point detected at end of sentence 1. w(n, n+1) values for each of these points are w(1, 2) = (2*2) = 4 and w(2, 3) = (1*0) = 0

MATERIALS AND METHODS

In this study, we present an evaluation of our segmenter SeLeCT. We discuss the evaluation metrics and our decisions regarding the choice of segments making up the corpus.

Corpus: In most test collections used as input to segmentation algorithms a lot of time and effort is spent gathering human annotations i.e. human judged topic shifts. The problem with these annotations lies in determining their reliability since human judges are notoriously inconsistent in their agreement on the beginning and end points of subtopic boundaries (Passoneau and Litman, 1993). A different approach to segmentation evaluation is available to us in our experiment due to the nature of the segments that we wish to detect. By concatenating distinct CNN broadcast news stories from various CNN news programmes (Night Time, DayLight, International News etc.) and using this as our test set, we eliminate subjectivity from our boundary judgments. So in this case a boundary can be explicitly defined as the joining point between two news stories, in contrast with other test collections, which contain (disjoint) lengthy articles consisting of many subjective subtopic segments. For example, Hearst (1997) originally evaluated her TextTiling algorithm on thirteen 'Stargazer' magazine articles which satisfied a certain length criteria (1800-2500 words). In comparison each news stories in our collection contains roughly 500 words. Finally our corpus consists of 1001 transcripts, however we only evaluate on the first 1000 boundary end points since finding the end point of the last document in the input stream is a trivial task.

Evaluation metrics: We used the standard precision and recall metrics in our evaluation of text segmentation. These metrics are more commonly used in IR evaluations to measure the ratio between the number of relevant retrieved documents by the IR system and the actual true

number of relevant documents (recall) and the number of relevant retrieved documents as a portion of the total number of relevant and non-relevant documents retrieved by the system (precision). Generally speaking the dynamic between these 2 measures is such that, if the recall of the system is increased (presumably by changing appropriate parameters within the algorithm) the precision of the system will drop and visa versa. In the case of system segmentation evaluation we define recall and precision as follows:

- Recall-the number of correctly detected end of news story boundaries as a proportion of the number of actual end of news story boundaries in the test set.
- Precision-the number of correctly detected end of news story boundaries as a proportion of the total number of boundaries returned by the segmentation algorithm.

RESULTS

Table 1 shows optimal results obtained for the three segmentation systems that took part in our evaluation:

- The benchmark system: That randomly returns boundary positions i.e., results represent a lower bound on performance.
- The SeLeCT system: A lexical chaining approach to segmentation described in detail in this study.
- TextTiling: The version of TextTiling we use in this experiment is JTextTile (Choi, 1997), a more efficient java implementation of Hearst's algorithm. Although Hearst recommends window size = 120 and pseudo sentence size = 20, optimal results were achieved using system parameters: window size = 500 and pseudo-sentence size = 20.

Results from Table 1 shows variations in precision and recall values using the following error function where s is a system boundary point, b is an actually boundary point and n is the distance in sentences between the actual boundary b and the system boundary s.

$$f(x) = 1 \quad \text{if } s+/-[0-n] = b$$
$$f(x) = 0 \quad \text{Otherwise}$$

For example in the case of n = 5 if the system boundary is s = 7 then the 'correctly detect boundary' score will be incremented if an actually boundary b exists between sentence numbers in the range from 2-12. The only stipulation on this increment is that sentences boundaries may only be detect once, which takes care of the case where a system boundary might match more than one boundary when the value of n is high. From Table 1, we also observe that our lexical chaining based segmenter SeLeCT significantly outperforms both our benchmark and JTextTile systems.

Table 1: Precision and recall values from segmentation on concatenated CNN news stories

	SeLeCT		JtextTile		Random segmentation	
Error	Recall	Precision	Recall	Precision	Recall	Precision
+/-0	62.7	36.6	19.7	13.3	7.1	7.1
+/-1	69.2	40.4	61.6	41.5	18.4	18.4
+/-2	77.4	45.2	79.9	53.8	29.4	29.4
+/-3	81.3	47.5	88.4	59.5	39.1	39.1
+/-4	84.3	49.2	94.1	63.4	45.9	45.9
+/-5	85.4	49.9	96.2	64.8	51.5	51.5
+/-6	87.4	51.0	97.3	65.5	55.7	55.7
+/-7	88.3	52.7	97.8	65.9	59	59
+/-8	89.3	52.1	98.2	66.1	62.4	62.4
+/-9	89.9	52.5	98.3	66.2	64	64

CONCLUSION

In this study, we have presented a lexical cohesion based approach to course-grained segmentation of CNN news transcripts resulting in the detection of distinct stories. We have shown that the performance of the SeLeCT system exceeds that of the JTextTile system when exact match story boundaries are required. The next step in our research is to re-evaluate this technique in a real news stream environment. We expect similar high levels of segmentation accuracy will be more difficult to replicate, as closed caption transcripts (in our case teletext) are less informative than CNN speech transcripts. News subtitles are effectively summaries of the audio content of news programme and are dependent on visual cues like speaker change to be fully understood. This lose in information will reduce the internal cohesive strength within stories making subtopics within these stories appear less related than they actually are i.e. this favours fine-grained segmentation.
