Abstract: The emerging technology of ad-hoc sensor networks helped to increase researches in this field due to a large number of applications that uses wireless ad hoc networks such as monitoring of the environment, intelligent agriculture, structure health, earthquake prediction, industrial control and target detection in military applications. Various analyses have been suggested for optimality of ad hoc networks; in our study for a given number of nodes we use a comparative analysis by using two kinds of sensors network, the first network with different type of sensors having different connectivity range and sensing coverage and the other network with same capabilities for sensors in terms of connectivity and coverage range and the aim is to have a clear view about the utility of deploying homogeneous or inhomogeneous wireless ad hoc sensor network. Analysis of sensors deployment with a homogeneous transmission range reveals better network connectivity. Therefore, deploying sensor nodes with different transmission range does not improve the connectivity of the network when a power constraint present. In addition, using inhomogeneous nodes does not help to reduce power consumption to maintain network availability.

Key words: Wireless ad-hoc networks, network connectivity, power consumption, phase transition, inhomogeneous, target detection

INTRODUCTION

The Wireless Sensor Networks (WSN) coverage and connectivity are necessary because good coverage means receiving reliable information from the monitored place by the network deployed in the monitored field, therefore, connectivity between nodes play an essential role in network connectivity. Ad-hoc (WSN) try to communicate with each other using multi-hop manner in order to deliver a packet of data sent from source to the base unit or the sink, the effect of environmental parameters and constraints of power consumption in these small sensors lead to counter many difficulties in terms of coverage or connectivity (Akyildiz and Vuran, 2010). These large numbers of randomly separated tiny nodes are power constrained and deployed to monitor multiple sensed things; hence, they need to remain active for a long time. Signal processing, idle listening and transmitting-receiving of the signal are the main reasons for power consumption. Therefore, the main challenge in the design of sensor networks is energy conservation. Furthermore, since, nodes are planned to be deployed in the area for a long time, serious problems can be encountered in the network if a node does not work

properly. In this study, analysis is carried out for the connection in the ad hoc network whose nodes are connected wirelessly and then graph theory concepts are considered to analyze whether wireless sensor nodes can be used to communicate wirelessly with each other where as connectivity doesn't certainly mean coverage or vice versa. Power saving might occur if the sensing range is reduced or statements of some sensor nodes are changed from active to idle which needs manipulating some complex protocols.

Literature review: Recent years have witnessed many types of research in ad-hoc wireless sensor networks connectivity and coverage related issues, a brief revision for existing works will be present as follows; coverage and connectivity studies have shown by Xing *et al.* (2005) Ammari and Das (2008) and Khanjary *et al.* (2014) proved that when transmitting range is at least twice sensing range then the nodes are connected if the coverage is guaranteed.

The researcher by Philips *et al.* (1989) approved that the possibility of adjacent nodes number must increase logarithmically with network region to have a connected network; the presence of a critical value was also seen for

the required amount of the nearest neighbors of the node with an infinite linked component in an infinite region. Miorandi and Altman (2005) developed a way of calculating the probability of isolation for network nodes during the existence of channel randomness for distributed nodes. By Liu the researchers presented: full, partial and limited connectivity coverage. It has been shown that two simple network topologies meet the limited coverage of the connectivity criterion. The minimum density of nodes required for the establishment of a connected wireless network for Rayleigh fading channels was shown according to the results obtained, the wireless sensor network connectivity degraded due to the fading effect. Researcher by Dung and An (2015) and Dousse *et al.* (2002) studied randomly distributed multi-hop wireless networks connectivity but the closest work to the one described in this research is Dousse *et al.* (2002) he investigated nodes with two assignments homogeneous and in homogeneous range.

The researcher by Kong and Yeh (2007) Dousse *et al.* (2002) and Lu *et al.* (2012) studied the percolation model and the continuum percolation model particularly for the analysis of large-scale wireless ad-hoc networks they showed if the nodes are spread at low density then the network will be divided into small fragments, if it has an extremely big connected component then the network can be considered to be percolated. The critical phase transition for large scale wireless ad hoc networks was investigated by Xing and Wang (2008) when the network topology experiences fragmenting due to increased random node failures, the phenomenon of phase transition can be defined as a sudden and extreme change from a subcritical to a supercritical phase.

MATERIALS AND METHODS

The graph theory by Diestel (2016) describes a graph as a pair of sets where the components are the points of the graph and a component requires a neighbor in order to stay connected and also a graph is referred to as a directed graph if the edges connecting the points are one-way; else, the graph can be considered undirected graph.

Large scale nodes which are randomly distributed is considered in this study and (Poisson point process) assumption is used to describe the location of the sensor nodes, stationary homogeneous spatial Poisson point process is satisfied by the following conditions as mentioned by Chiu *et al.* (2013) and Chen *et al.* (2018). Points that occur in side a limited Area (Ax) is a random variable with mean $\varphi|Ax|$ that uses a Poisson distribution for constant φ where $|Ax|$ is the area of Ax.

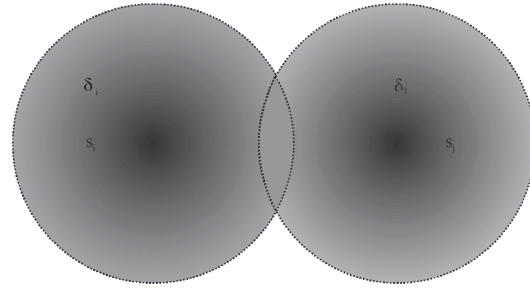

Fig. 1: A graphical design of wireless sensors nodes communication

Total number presumed in the points (m) that taking place in (Ax), locations of the (m) points describe a (self-determining) random sample of (m) positions where every position has an equal probability to be selected in the region.

Therefore, the constraint of the Poisson process to the region (Ax) with a condition that Ax has m points returns a binomial process for m point which is outlined assuming that the arbitrary point (a) is distributed uniformly in the area (Ax) if:

$$P_n(a \in b) = \frac{|b|}{|Ax|} \quad (1)$$

For all regions (b) in Ax. The power of the binomial process for the points is characterized by and given by:

$$\varphi = \frac{m}{|Ax|} \quad (2)$$

Simulation model and assumptions: The study scenario will presume that X nodes are installed in an x area. The node density will then be equal to:

$$\varphi = \frac{X}{(L_s)^2} \quad (3)$$

Some modeling assumptions are outlined in Fig. 1. Let $Z_\varphi = \{\delta_i; i \geq 1\}$ represent “two dimensional homogeneous Poisson point process” Khanjary *et al.* (2014) with density φ where δ_i represents the location of the sensor s_i . Let $Z_\varphi(L_s)$ be an a random variable that represent the number of the points in a defined area $b = L_s \times L_s$ then the probability of having X points inside b is computed as:

$$p(Z_\varphi(L_s) = X) = \frac{\varphi^X |b|^X e^{-\varphi|b|}}{X!} \quad (4)$$

For all $X \geq 0$ where $|b|$ is the size of b s area. The setup of the network in the simulation scenario is arranged by using two kinds of sensor nodes; the first model has a Small Communication Range (SCR) and the sec model has a Large Communication Range (LCR). It is worthy to mention here that the use of such kinds of nodes that have large transmission capability will lead to consuming more power.

Since, the study uses two kinds of nodes in sensor deployment, therefore, two plans for placement of nodes are tested; (homogeneous) and (Inhomogeneous) sensor nodes (in terms of communication range). For simulation determinations, the exponent of path loss λ is set to 3. Nodes randomly deployed using 80, 160, 320 and 640 sensor nodes and the effects of placing these types of nodes on the connectivity of the deployment region were investigated (Table 1).

Table 1: The parameters used to obtain simulation results

Parameters	Notations	Values
Large communication range node	Lc_r	(try 1) $Lc_r = 3-50$ m (try 2) $Lc_r = 7-50$ m
Small communication range node	Sc_r	(try 1) $Sc_r = 3$ m (try 2) $Sc_r = 7$ m
LCR nodes ratio	L_r	{0.06, 0.12, 0.24, 0.48}
Nodes deployment number	N_d	{80, 160, 240, 320, 400}
The assumed exponent of path loss	λ	3
The assumed area size	La	100×100 m
Homogeneous nodes range	S_r	(0, 2, 4, 5, 6, ..., 18 m)

Table 2: The ratio Lc_r/Sc_r for energy ratio equal to 2

Ratio of L_r /Ranges (m)	$L_r = 0.06$	$L_r = 0.12$	$L_r = 0.24$	$L_r = 0.48$
$Sc_r = 3$	$Lc_r/Sc_r = 17.5$	$Lc_r/Sc_r = 13.9$	$Lc_r/Sc_r = 11.1$	$Lc_r/Sc_r = 7.4$
$Lc_r = 3-50$				
$Sc_r = 7$	$Lc_r/Sc_r = 5.7$	$Lc_r/Sc_r = 4.4$	$Lc_r/Sc_r = 3.6$	$Lc_r/Sc_r = 2.5$
$Lc_r = 7-50$				

RESULTS AND DISCUSSION

Figure 2 displays the results for network simulations of wireless sensors with pure homogeneous nodes. It is clearly can be seen that the connectivity is higher when more nodes are used. Sensor nodes connectivity range has also its influence. It reaches almost 100% when $N_d = 400$. The network connectivity increases sharply after a certain point, this phenomenon is called (phase transition) which is a sudden change of small disconnected clusters to turn into a single large connected component (Xing and Wang, 2008).

On the other hand, the scenario of using inhomogeneous nodes has shown interesting results, nodes with different transmission ranges LCR and SCR have been used in the simulation with the given environment. Requirements of power consumption will be considered to evaluate the plan the energy consumption of homogeneous sensor nodes deployment is equivalent to Sr^λ (Table 2). The energy consumed by inhomogeneous nodes and homogenous distribution $(1-L_r) Sc_r^\lambda + L_r(Lc_r)^\lambda$. The energy ratio in the (Homogeneous) case to that in (Inhomogeneous) case is determined by:

$$\text{Energy consumption ratio} = \frac{(1-L_r)Sc_r^\lambda + L_r(Lc_r)^\lambda}{(S_r)^\lambda} \quad (5)$$

Figure 3 the energy ratio with a communication range $Sc_r = 3$ m for (SCR) sensor nodes and from $Lc_r = 3$ m to

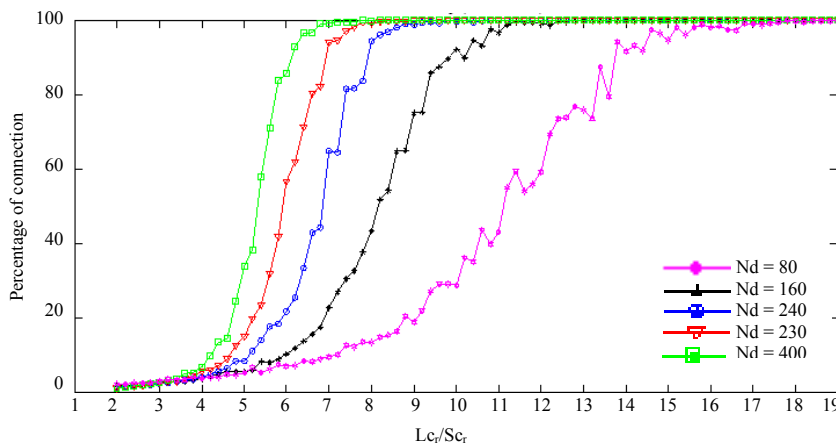

Fig. 2: Measurements of connectivity by using homogeneousness or node sat $N_d = (80, 160, 240, 320$ and $400)$ in the network (calculation of average more than 30 runs)

$L_c = 50$ m for (LCR) sensor nodes and the homogeneous communication range = 8 m with a path loss exponent configured to be Eq. 3. The energy ratio rises rapidly as can be seen in Fig. 4 when the ranges of S_c enlarged from 3-7 m and L_c from 3-7 m as well comparing to the ratio of the LCR nodes.

By defining the energy consumption ratio equivalent to Eq. 2, the installation strategy of using two types of sensor nodes could be compared as Table 2 summarizes L_c/S_c identified with Fig. 3 and 4 in inhomogeneous cases.

A critical range is a range needed to connect the sensor node network. If any sensor's range is smaller than

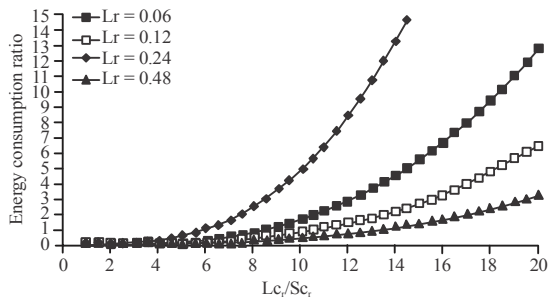

Fig. 3: Ratio of consumed energy by sensor nodes at $\lambda = 3$, $S_c = 8$ m, $S_r = 3$ m, $L_c = 3-50$ m

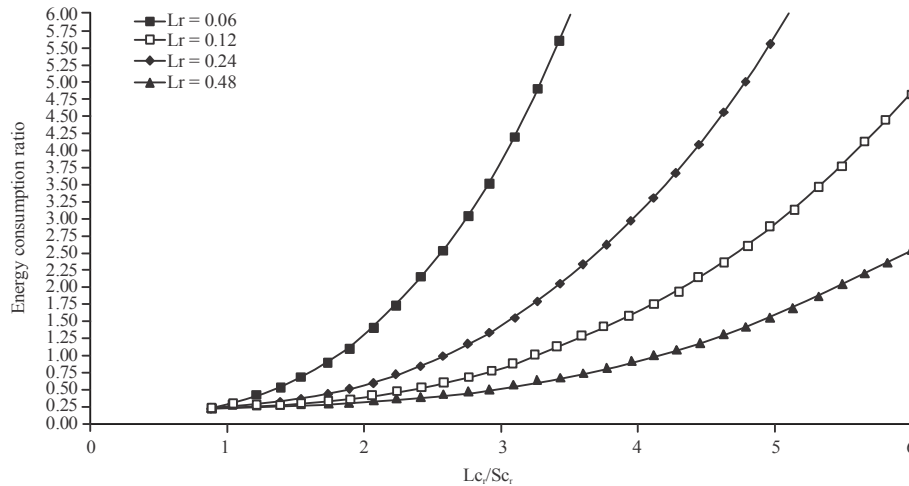

Fig. 4: Ratio of consumed energy by nodes at $\lambda = 3$, $S_r = 8$ m, $S_c = 7$ m, $L_c = 7-50$ m

the critical range, even if the other range is very high, a connected network cannot be achieved. Similar findings for undirected graph networks were founded by Bettstetter (2002).

The level of connectivity improves when we make the LCR nodes approach 48% of the total nodes deployed but have not yet reached 100% of connectivity as shown in Fig. 5 and 6. Although, 400 sensor nodes are distributed, the desired connectivity is still below the target level. Figure 5 shows that connectivity barely exceeds 70% when the LCR node ratio is 0.48 and is lower for ratios (0.06, 0.12 and 0.24) with node numbers 80, 160 and 320. Table 3 shows the summarized results when and compared to homogeneous deployment results Fig. 5 and 6 are just two samples from the obtained results which are summarized in Table 3.

After using nodes with a range $S_c = 3$ m as shown in Fig. 5 and 6 the behavior is approximately similar when the range increases to $S_c = 7$ m as presented in Fig. 7 and 8 which are samples for the found results. Table 4 reviews the results of using in homogeneous strategy for deployment when the ranges are $S_c = 8$ m and $L_c = 7-50$ m.

From all the results and caparisons that carried out, it is clear that the homogeneous deployment strategy

Table 3: The comparison of inhomogeneous results at $L_c = 3-50$ m, $S_c = 3$ m with homogenous results

No. of deployed nodes	Homogeneous nodes connection (%) when $S_r = 8$ m	Ratio of LCR/LCR models				
		Ratio of L_c/S_c (m)	L_r 0.06 (%)	L_r 0.12 (%)	L_r 0.24 (%)	L_r 0.48 (%)
			Inhomogeneous communication range	$L_c/S_c = 17.5$	$L_c/S_c = 13.9$	$L_c/S_c = 11.1$
$N_d = 80$	14.0	$L_c = 3-50, S_c = 3$	5	7	11	35
$N_d = 160$	44.0	$L_c = 3-50, S_c = 3$	5	11	23	66
$N_d = 240$	94.0	$L_c = 3-50, S_c = 3$	7	14	26	67
$N_d = 320$	98.0	$L_c = 3-50, S_c = 3$	8	15	29	72
$N_d = 400$	99.9	$L_c = 3-50, S_c = 3$	9	16	32	72

shows better communication network and performance. Furthermore, there is an enormous difference between the statistics representing the connection among sensor nodes of the homogeneous and in homogeneous distribution cases with the range Sc_r and Lc_r initialized with 3 m. The second try and (Sc_r and Lc_r initialized with 7 m) presents grater ratio of connectivity with a great amount of nodes.

It can be explained as follows; the first try results came by using low communication range. Furthermore,

with 3 m for Sc_r and from 3-50 m for Lc_r . Hence, many sensors have been out of range due to small communication ranges in particular the sensors with Sc_r .

It seems that the sensors with Sc_r look like undercritical range, therefore, full connected network could not be obtained. Both types of nodes must exceed a certain critical range for a connected network. These observations correspond to observations Bettstetter, (2002).

CONCLUSION

In this study, connectivity assessment is performed using inhomogeneous and homogeneous deployment strategy for ad-hoc sensors. Two strategies, homogeneous and inhomogeneous are evaluated to determine the higher connectivity. Consumption of power was considered in both. The simulations reveal that the network shows better connectivity when homogeneous sensor deployments are used rather than using inhomogeneous sensors network forming as a directed graph varied from previous analysis using undirected graphs. Phase transition has been shown in the network which used directed graphs in the simulation. At last, after manipulating many simulations, it's clear that the networks with homogeneous sensors deployments offer greater communication capabilities between nodes for limited energy. The study confirmed previous works that investigated wireless ad hoc network communication properties. Future research may involve the development of the network's directed graph model for further investigation of network connectivity properties. In addition, a specific deployment strategy for ad-hoc networks also requires more complex energy consumption and power constraint models to be used in future works.

NOTATIONS

- b : Sub-region of A_x
- A_x : Finite region
- $|A_x|$: Area of region A_x
- Z_β : 2D homogeneous Poisson point process
- L_s : Side-length of the region
- X : The No. of sensors
- φ : Nodes density
- λ : Exponent factor of the path loss
- P_n : The path between the two sensors
- P : Probability of having (LCR) sensors

- s_i, S_j : Arbitrary sensor nodes
- a : Random point
- LCR : Large Communication Range sensor
- SCR : Small Communication Range sensor
- Z_β : Location of sensors s_i and s_j
