A New Fuzzy Clustering Algorithm on Association Rules for Knowledge Management

Pi Dechang and Qin Xiaolin

College of Information Science and Technology, Nanjing University of Aeronautics and Astronautics, Yudao Street 29, Nanjing, Jiangsu, 210016, People's Republic of China

Abstract: A great number of association rules found in the dataset makes the decision maker dizzy to analyze and use. A new algorithm for association rules clustering is proposed and applied to association rules clustering. Firstly, an example is presented to demonstrate the weakness by the distance measure for clustering. Secondly, the definition of fuzzy simulation degree and simulated matrix for association rules are put forward. Thirdly, a new algorithm based on a dynamic tree is brought forward, which can be used to implement the fuzzy clustering. Experiment shows that this algorithm can efficiently cluster the association rules for a user to understand.

Key words: Fuzzy clustering analysis, association rule, knowledge management

INTRODUCTION

Association rule is a focus in the data mining area recently; meanwhile, it is a way to express the knowledge. Fuzzy set theory has been applied to many fields including data mining. Fuzzy clustering method is more precise in dealing with data simulation and the results are easier to be understood and used. Therefore, research into fuzzy clustering method for knowledge is significant not only to theory, but also to application. Many fuzzy clustering methods have already been proposed and used in data mining. Fuzzy clustering with squared Minkowski distances was proposed in (Groenen and Jajuga, 2001). Fuzzy c-means method was used in dynamic data mining (Corespao and Weberb, 2005). Clustering algorithm based on self-similarity of the dataset was suggested in (Barbara and Chen, 2003). Fosca Giannotti et al. (2002) cluster transactional data with the standard definition of mathematical distance used in the K means algorithm to represent dissimilarity among transactions. Hirano and Tsumoto (2003) cluster a numerical dataset using relative proximity. Oh and Lee (2003) use clustering method to detect any anomalous behavior in the audit data. Grabmeier and Rudolph (2002) gives an overview of cluster analysis techniques from a data-mining point of view. Xiaoyong et al. (1999) presents a method to select some, representative, rules but not a large number of rules for a user to understand. Clustering rules is necessary in merging multi-sources, which may contain conflicting knowledge and make us illusive currently (Zobel and Rees, 2005). From the literatures, we have not found any

methods to cluster association rules based on fuzzy simulation for a user to expediently understand.

Association rules are used to discover the relationships and potential associations, of items or attributes among huge amounts of data. These rules can be effective in uncovering the unknown relationships, providing results that can be the basis of forecast and decision. They have proven to be very useful. The application and development about association rules is a popular area of data mining research (Yuh-Jiuan and Jiunn-Yann, 2005).

Review of association rules and the classical mining algorithm: The early data mining method for association rules is the support-confidence framework established by Agrawal *et al.* (1993) and Agrawal and Srikant (1994). They proposed a model to discover meaningful itemsets and construct association rules for market analysis. The following is a formal statement of the problem.

Let $I = \{i_1, i_2, i_3, \dots, i_N\}$ be a set of N distinct literals, called items. In general, a set of items is called an itemset. The number of items in an itemset is the length of an itemset. Itemset of length k is referred to as a k-itemset. Let D be a set of variable length transactions, where each transaction T is a set of items such that $T \subseteq I$. Associated with each transaction is a unique identifier, which shall be referred to as its TID. |D| is the cardinality of database D. A transaction T is said to support an itemset X, where $X \subseteq I$, if it contains all items of X, i.e., $X \subseteq T$. The fraction of the transactions in D that support X is called the support of X, denoted Support(X). An itemset is large if

its support is above some user-specified minimum support threshold, denoted MinSup. An association rule is an implication of the form $r: X \to Y$, where $X \subset I$, $Y \subset I$ and $X \cap Y = \emptyset$. The support for rule r is defined as Support $(X \cup Y)$. A confidence factor defined as support $(X \cup Y)$ /support(X), is used to evaluate the strength of such association rules.

The process of Apriori mining association rule algorithm makes multiple passes over the database D to build candidate itemsets and then create large itemsets. In the kth level, the algorithm finds all large k-itemsets. Denoting L_k is the set of all large k-itemsets and C_k is the set of candidate k-itemsets by obtaining from L_{k-1}, that is, potentially large k-itemsets. For each transaction in D, the candidates in Ck also contained in the transaction are determined and their support is increased by 1/|D|. At the end of scanning, if their supports are greater than, or equal to, the user-specified minimum support (MinSup), the candidate k-itemsets immediately become the large k-itemsets. Meanwhile, it will generate a large number of the candidate itemsets that need to be contrasted with the whole database level by level in the process of mining the association rules. Therefore, performance is dramatically affected, as the database is repeatedly scanned. The most time-consuming part of the algorithm is to discover large itemsets while the generation of association rules given the large itemsets is straightforward enough. Many researchers have tried to improve its efficiency from different angles and decreased the number of database the number of candidate itemsets. scans and (De-Chang et al., 2005; Yuh-Jiuan and Jiunn-Yann, 2005).

A common problem in association rule mining is that a large number of rules are generated from the datasets, which makes it difficult for users to analyze and make use of the rules. Solutions have been proposed to overcome this problem, which include constraint-based data mining, post-pruning rules, grouping rules (Yih-Jen *et al.*, 2005) and unexpected patterns based on user's beliefs (Padmanabhan and tozhilin, 1999).

Related research on fuzzy clustering: Currently, most of the commercial clustering systems are based on the boolean logic model. They assume that a user's requirements can precisely be characterized by the terms. However, this assumption is inappropriate due to the fact that the user's requirements may contain fuzziness. The reason for the fuzziness contained in the user's requirements is that the user may not know much about the subject he/she is clustering or may not be familiar with the clustering system. Since fuzzy set theory can be used to describe imprecise or fuzzy information, many researchers have applied the fuzzy set theory to many systems including clustering (Ravi and Gowda, 1999; Yih-Jen *et al.*, 2005).

The objective of fuzzy clustering methods is to divide a given dataset into a set of clusters based on similarity (Timm et al., 2004). In classical cluster analysis each datum must be assigned to exactly one cluster. Fuzzy cluster analysis relaxes this requirement by allowing membership degrees, thus offering the opportunity to deal with data that belong to more than one cluster at the same time. Most fuzzy clustering algorithms are objective function based: they determine an optimal classification by minimizing an objective function. In objective function based clustering usually each cluster is represented by a cluster prototype. This prototype consists of a cluster center and maybe some additional information about the size and the shape of the cluster. The cluster center is an instantiation of the attributes used to describe the domain, just as the data points in the dataset to divide. However, the cluster center is computed by the clustering algorithm and may or may not appear in the dataset. The size and shape parameters determine the extension of the cluster in different directions of the underlying domain.

The degrees of membership to which a given data point belongs to the different clusters are computed from the distances of the data point to the cluster centers. The closer a data point lies to the center of a cluster, the higher is its degree of membership to this cluster. Hence, the problem to divide a dataset $X = \{x_1, ..., x_n\}$ into c clusters can be stated as the task to minimize the distances of the data points to the cluster centers. An iterative algorithm is used to solve the classification problem in objective function based clustering: since the objective function cannot be minimized directly, the cluster prototypes and the membership degrees are alternately optimized.

Defects in association rules clustering based on distance: Clustering methods based on distance, such as Euclid distance, Minkowski distance and Hamming distance often have some limitations and they cannot effectively deal with the association rules clustering.

Usually association rules are denoted as the form: $X \Rightarrow Y$, in which X and Y are often expressed as X_1 and X_2 and ... and X_n . As aforementioned, association rule is a way for knowledge expression and there are some similarities among them. For example, the following two rules are discovered from the zoo dataset in the UCI Machine Learning Database Repository.

Rule 1: if backbone = true and breathes = true and venomous = false then fins = false

Rule 2: if backbone = true and venomous = false and fins = false then breathes = true

Obviously we can find some similarities between the two rules. From the antecedent attributes of these rules we can cluster them in terms of similarities. The core problem is how to depict the simulation degree between these rules. Suppose that there are four rules as follows:

- r_1 : X_1 and X_2 and X_3 and $X_5 \Rightarrow$ conclusion 1
- r₂: X₂ and X₃ and X₄ and X₅ ⇒ conclusion 2
- r₃: X₁ and X₄ ⇒ conclusion 3
- r₄: X₆ ⇒ conclusion 4

In the premise, let X_i appearing denotes 1 and non-appearing denotes 0. Using Euclid distance, the simulation coefficient between two rules is expressed with distance d, as follows:

- $d(r_1, r_2) = 1.414$
- $d(r_1, r_3) = 2$
- $d(r_1, r_4) = 2.23$
- $d(r_2, r_3) = 2$
- $d(r_2, r_4) = 2.23$
- $d(r_3, r_4) = 1.73$

Obviously rule r_1 and rule r_2 should belong to the same class in terms of the distance clustering method, because the distance between them is minimal. After clustering, we denote this class as R_1 and its center of gravity is (0.5, 1, 1, 0.5, 1, 0). In the same way, we can compute the distances between R_1 and other rules:

- $d(R_1, r_3) = 1.87$
- $d(R_1, r_4) = 2.12$
- $d(r_3, r_4) = 1.73$

Obviously rule r_3 and rule r_4 should be clustered to the same class because the distance between them is minimal. But considering from the attributes appeared in r_3 and r_4 , we should not make them belong to the same class because they do not have the same attributes. This result indicates that current clustering methods based on distance are not suitable for rules clustering. Until now, we have not found same literature to cluster association rules for a user to understand on the view of knowledge management.

Based on the research on association rules and fuzzy clustering, we bring forward the FCAR algorithm for association rules clustering.

FUZZY CLUSTERING ALGORITHM BASED ON RULE SIMULATION

Fuzzy clustering is partitioning n objects into K subsets, which are called as clustering dollop. The clustering result can be denoted by the membership degree matrix U.

$$U_{s\times n} = (u_{ik})_{s\times n} = \begin{pmatrix} u_{11}, & \dots, & u_{1n} \\ u_{i1}, & \dots & u_{ik}, & \dots & u_{in} \\ u_{s1}, & \dots, & u_{sn} \end{pmatrix}$$

Where, $u_{ik} \in [0, 1], 1 \le i \le s, 1 \le k \le n$

For clustering methods based on fuzzy similar relation, the first step is to construct the fuzzy simulated matrix, however the key of this step is how to define the simulation coefficient, which can reflect the similarity between two objects. At present, there are many methods that can be used to express simulation coefficient, such as maximum-minimum method. But they cannot describe the simulation between rules and are not appropriate to rule clustering just as Euclid distance method.

Some definitions: We bring forward the concept and definition of rule simulation coefficient in terms of expressions of association rules.

Definition 1: Rule r is expressed in this form: $X \rightarrow Y$, where X and Y denote AND relation between attributes, namely A_i and ... and A_k.

Definition 2: $\|r_u \wedge r_v\|$ is the number of attributes, which appear in the antecedents of rule r_u and r_v at the same time.

Definition 3: $\|\mathbf{r}_{\mathbf{u}} \vee \mathbf{r}_{\mathbf{v}}\|$ is the number of attributes, which appear in the premise of rule $\mathbf{r}_{\mathbf{u}}$ and $\mathbf{r}_{\mathbf{v}}$.

Definition 4:

$$\mathbf{c}_{\mathtt{u}\mathtt{v}} = \frac{\left\|\mathbf{r}_{\mathtt{u}} \wedge \mathbf{r}_{\mathtt{v}}\right\|}{\left\|\mathbf{r}_{\mathtt{u}} \vee \mathbf{r}_{\mathtt{v}}\right\|}$$

is the fuzzy simulation coefficient between rule $r_{\scriptscriptstyle u}$ and rule $r_{\scriptscriptstyle v}$. Apparently, the bigger $c_{\scriptscriptstyle uv}$ is, the more similar the rules are and vice versa.

Definition 5: Rule fuzzy simulated matrix $C = (c_{uv})_{n \times n}$ denotes simulation degree between rules.

Matrix C expresses the simulation degrees between different rules. The c_{uv} represents the simulation degree of uth rule to vth rule and it satisfies the follow demands:

c_{uv} ∈[0, 1]
Reflexivity: ∀u, v, C_{uv} = 1, if u = v
Symmetry: ∀u, v, C_{uv} = C_{vuv}, if u ≠ v

Clustering method based on fuzzy simulation coefficient:

Our algorithm FCAR combines rule simulation coefficient with dynamic construction tree method. Its general steps can be described as follows:

- Use association rules to construct simulated matrix.
- Construct a tree.
- Prune the tree according to the user-specified threshold and then get the clustering results.

Let $N = (V, \{E\})$ be the storage form for the simulated matrix, where V is a set of the rules, $\{E\}$ is a set of the branches among rules. Let U be a non-empty subset of V and TE be a set of the branches about N. Clustering algorithm based on the simulation coefficient is described as follows:

$$U = \{u_n\}, \text{ where } u_n \in V$$

```
\begin{split} TE &= \varnothing; \\ WHILE~U \neq V~DO \\ BEGIN \\ &\quad Find~a~maximal~c_{u0v0},~where~u_0 \in U,~v_0 \in V\text{-}U \\ &\quad Execute~TE = TE \cup \{(u_0,~v_0)\}~and~U = U \cup \{v_0\} \\ END \\ &\quad FOR~each~branch~b \in TE~DO \\ &\quad IF~b.value < the~user-specified~threshold~\lambda~THEN \\ &\quad Cut~down~this~connection \\ &\quad ENDIF \\ &\quad ENDFOR \end{split}
```

We still use these rules $r_1 \sim r_4$ mentioned earlier as example to indicate that our method has an advantage over the distance method. The fuzzy simulation coefficients between two rules can be expressed with simulation degree sd, as follows:

$$\begin{array}{l} sd\left(r_{1},\,r_{2}\right)=0.6\\ sd\left(r_{1},\,r_{3}\right)=0.2\\ sd\left(r_{1},\,r_{4}\right)=0\\ sd\left(r_{2},\,r_{3}\right)=0.2\\ sd\left(r_{2},\,r_{4}\right)=0\\ sd\left(r_{3},\,r_{4}\right)=0 \end{array}$$

and the simulated matrix C for these four rules is:

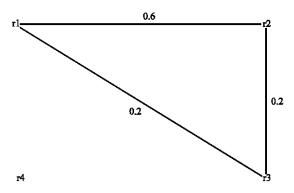

Fig. 1: Fuzzy simulation degree between rules $r_1 \sim r_4$

$$\mathbf{C} = \begin{pmatrix} 1 & & & \\ 0.6 & 1 & & \\ 0.2 & 0.2 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

The connection among these rules is described in Fig. 1 and the numbers on the line are the fuzzy simulation coefficients.

If user specified threshold be 0.5, obviously these four rules can be divided into three classes, $\{r_1, r_2\}$, $\{r_3\}$ and $\{r_4\}$. If the threshold be 0.2, we can get two sets, $\{r_1, r_2, r_3\}$ and $\{r_4\}$. Apparently, by employing c_{uv} , we can avoid the weakness of distance clustering and at the same time, we can control the clustering by adjusting the threshold of c_{uv} .

EXPERIMENT

As C++ STL is powerful, this fuzzy clustering algorithm is implemented with C++ STL, compiled with Microsoft Visual C++ 6.0. We use Apriori algorithm to mine association rules from the zoo dataset with different support and confidence. This dataset can be obtained from UCI Machine Learning Database Repository at http://www.ics.uci.edu/~mlearn/ MLRepository.html and it contains 101 records and 18 attributes. Table 1 shows the numbers of association rules generated from the dataset Zoo with different support and confidence.

If the thresholds for support and confidence are 0.5 and 0.9, respectively, 64 rules are found. The following four rules are examples and obviously they should be clustered into one class.

- If feathers = no and airborne = true and toothed = true then backbone = true and venomous = no support = 0.544554 confidence = 0.932203.
- If feathers = no and toothed = true and backbone = true then airborne = no and venomous = no support = 0.544554 confidence = 0.901639.

Table 1: No. of association rules mined from the Zoo dataset

	Minsup		
MinConf	0.5	0.6	0.7
0.9	64	19	6
0.8	120	34	10
0.7	165	50	12
0.6	203	56	12

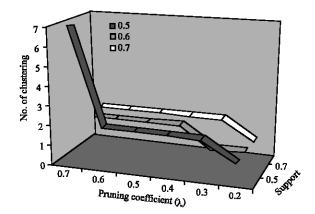

Fig. 2: Clustering the association rules discovered from the Zoo dataset

- If airborne = no and toothed = true then backbone = true and feathers = no and venomous = no support = 0.544554 confidence = 0.932203.
- If toothed = true then backbone = true and venomous = no and feathers = no and airborne = no support = 0.544554 confidence = 0.901639.

We use this algorithm to cluster the above 12 rules sets as shown in Table 1 as well as to prune the simulation tree with different pruning coefficient λ . Let the confidence threshold be 0.9, the range of λ be [0.2,0.7] and the range of support be [0.5,0.7], then we get the clustering results as shown in Fig. 2. With the pruning coefficient λ being 0.7, the numbers of the association rules clustering are 7, 2 and 2. If we change λ into 0.2, the clustering number will be 1.

CONCLUSIONS AND FURTHER WORK

Usually the number of association rules found by data mining algorithms is big. Although these rules have high supports and confidences, they are often pertained to some aspects and have higher similarity. Using this method we can categorize the association rules; hence they can be easily understood and used. The core of this research can be summarized as follows:

 Propose the definition c_{uv}, which denotes the fuzzy close degree between rule r_u and rule r_v.

- Define the simulated matrix.
- Put forward a clustering algorithm based on the simulated matrix, by which we can obtain different clustering results with different pruning coefficients.

We use Apriori algorithm to mine association rules from the Zoo dataset provided by the UCI and employ our algorithm to cluster these found rules. Experiment shows that this algorithm is efficient in clustering the association rules.

What we need to explain is, if the premise is out of the AND expression, we must translate it into the normal form. If the premise contains the NOT operator, our algorithm cannot run smoothly. We are studying the new method to resolve this problem.
